Abstract	<p>It is reported the application of the voltammetry of microparticles (VMP), complemented with attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) and field emission scanning electron microscopy (FESEM) techniques, to monitor the deterioration of verdigris pictorial specimens under the action of different biological agents. This methodology would be of application for identifying the type of biological agent causing deterioration of paintings, which is an important problem affecting cultural heritage. The analysis of biodeterioration processes is complicated by the fact that the action of microorganisms can affect both pigment and binding media. The deterioration of pictorial specimens combining verdigris with egg and egg-linseed oil binders by <i>Penicillium chrysogenum</i>, <i>Aspergillus niger</i>, <i>Acremonium chrysogenum</i>, <i>Trychoderma pseudokoningi</i> and <i>Mucor rouxii</i> fungi and <i>Bacillus amyloliquefaciens</i>, <i>Arthrobacter oxydans</i> and <i>Streptomyces cellulosans</i> bacteria were tested using sample-modified graphite electrodes immersed into aqueous electrolytes. A model is presented to describe the involved electrochemistry resulting in specific voltammetric features for the electrochemical reduction of verdigris associated to the proteinaceous and lipidic fractions of the binders. The experimental results and model proposed have been discussed and compared with those previously obtained for cadmium yellow reconstructed paint film specimens.</p>
